COMPARING INCIDENCE OF SURGICAL SITE INFECTION AFTER IRRIGATION WITH 0.05% CHLORHEXIDINE AND TRIPLE ANTIBIOTIC SOLUTION IN IMMEDIATE BREAST RECONSTRUCTION

INTRODUCTION

Postoperative wound infection with tissue expander (TE) breast reconstruction historically has a broad rate of 5-20% ¹⁻⁴. Majority of studie demonstrate about 12-16% infection rate. Brea pockets are thus generally irrigated with a varie of solutions to decrease bacterial load.

Triple antibiotic solution ((1 g of cefazolin, 50,0 U of bacitracin, and 80 mg of gentamicin in 500 of NS) is commonly used to decreases bacterial growth ^{5,6}. However, the concern is that antimicrobials work during bacterium logarithr growth phase.

0.05% chlorhexidine gluconate (CHG) is commo used to prep skin and known to be bactericidal contact with rapid and persistent activity again common bacteria such as Staphylococcus aurei and Escherichia coli among others.

Given this, we hypothesize that dilute chlorhexidine would decrease postoperative T infections. Partially inflated tissue expanded

Fig 1. Tissue Expander Placement

OBJECTIVES

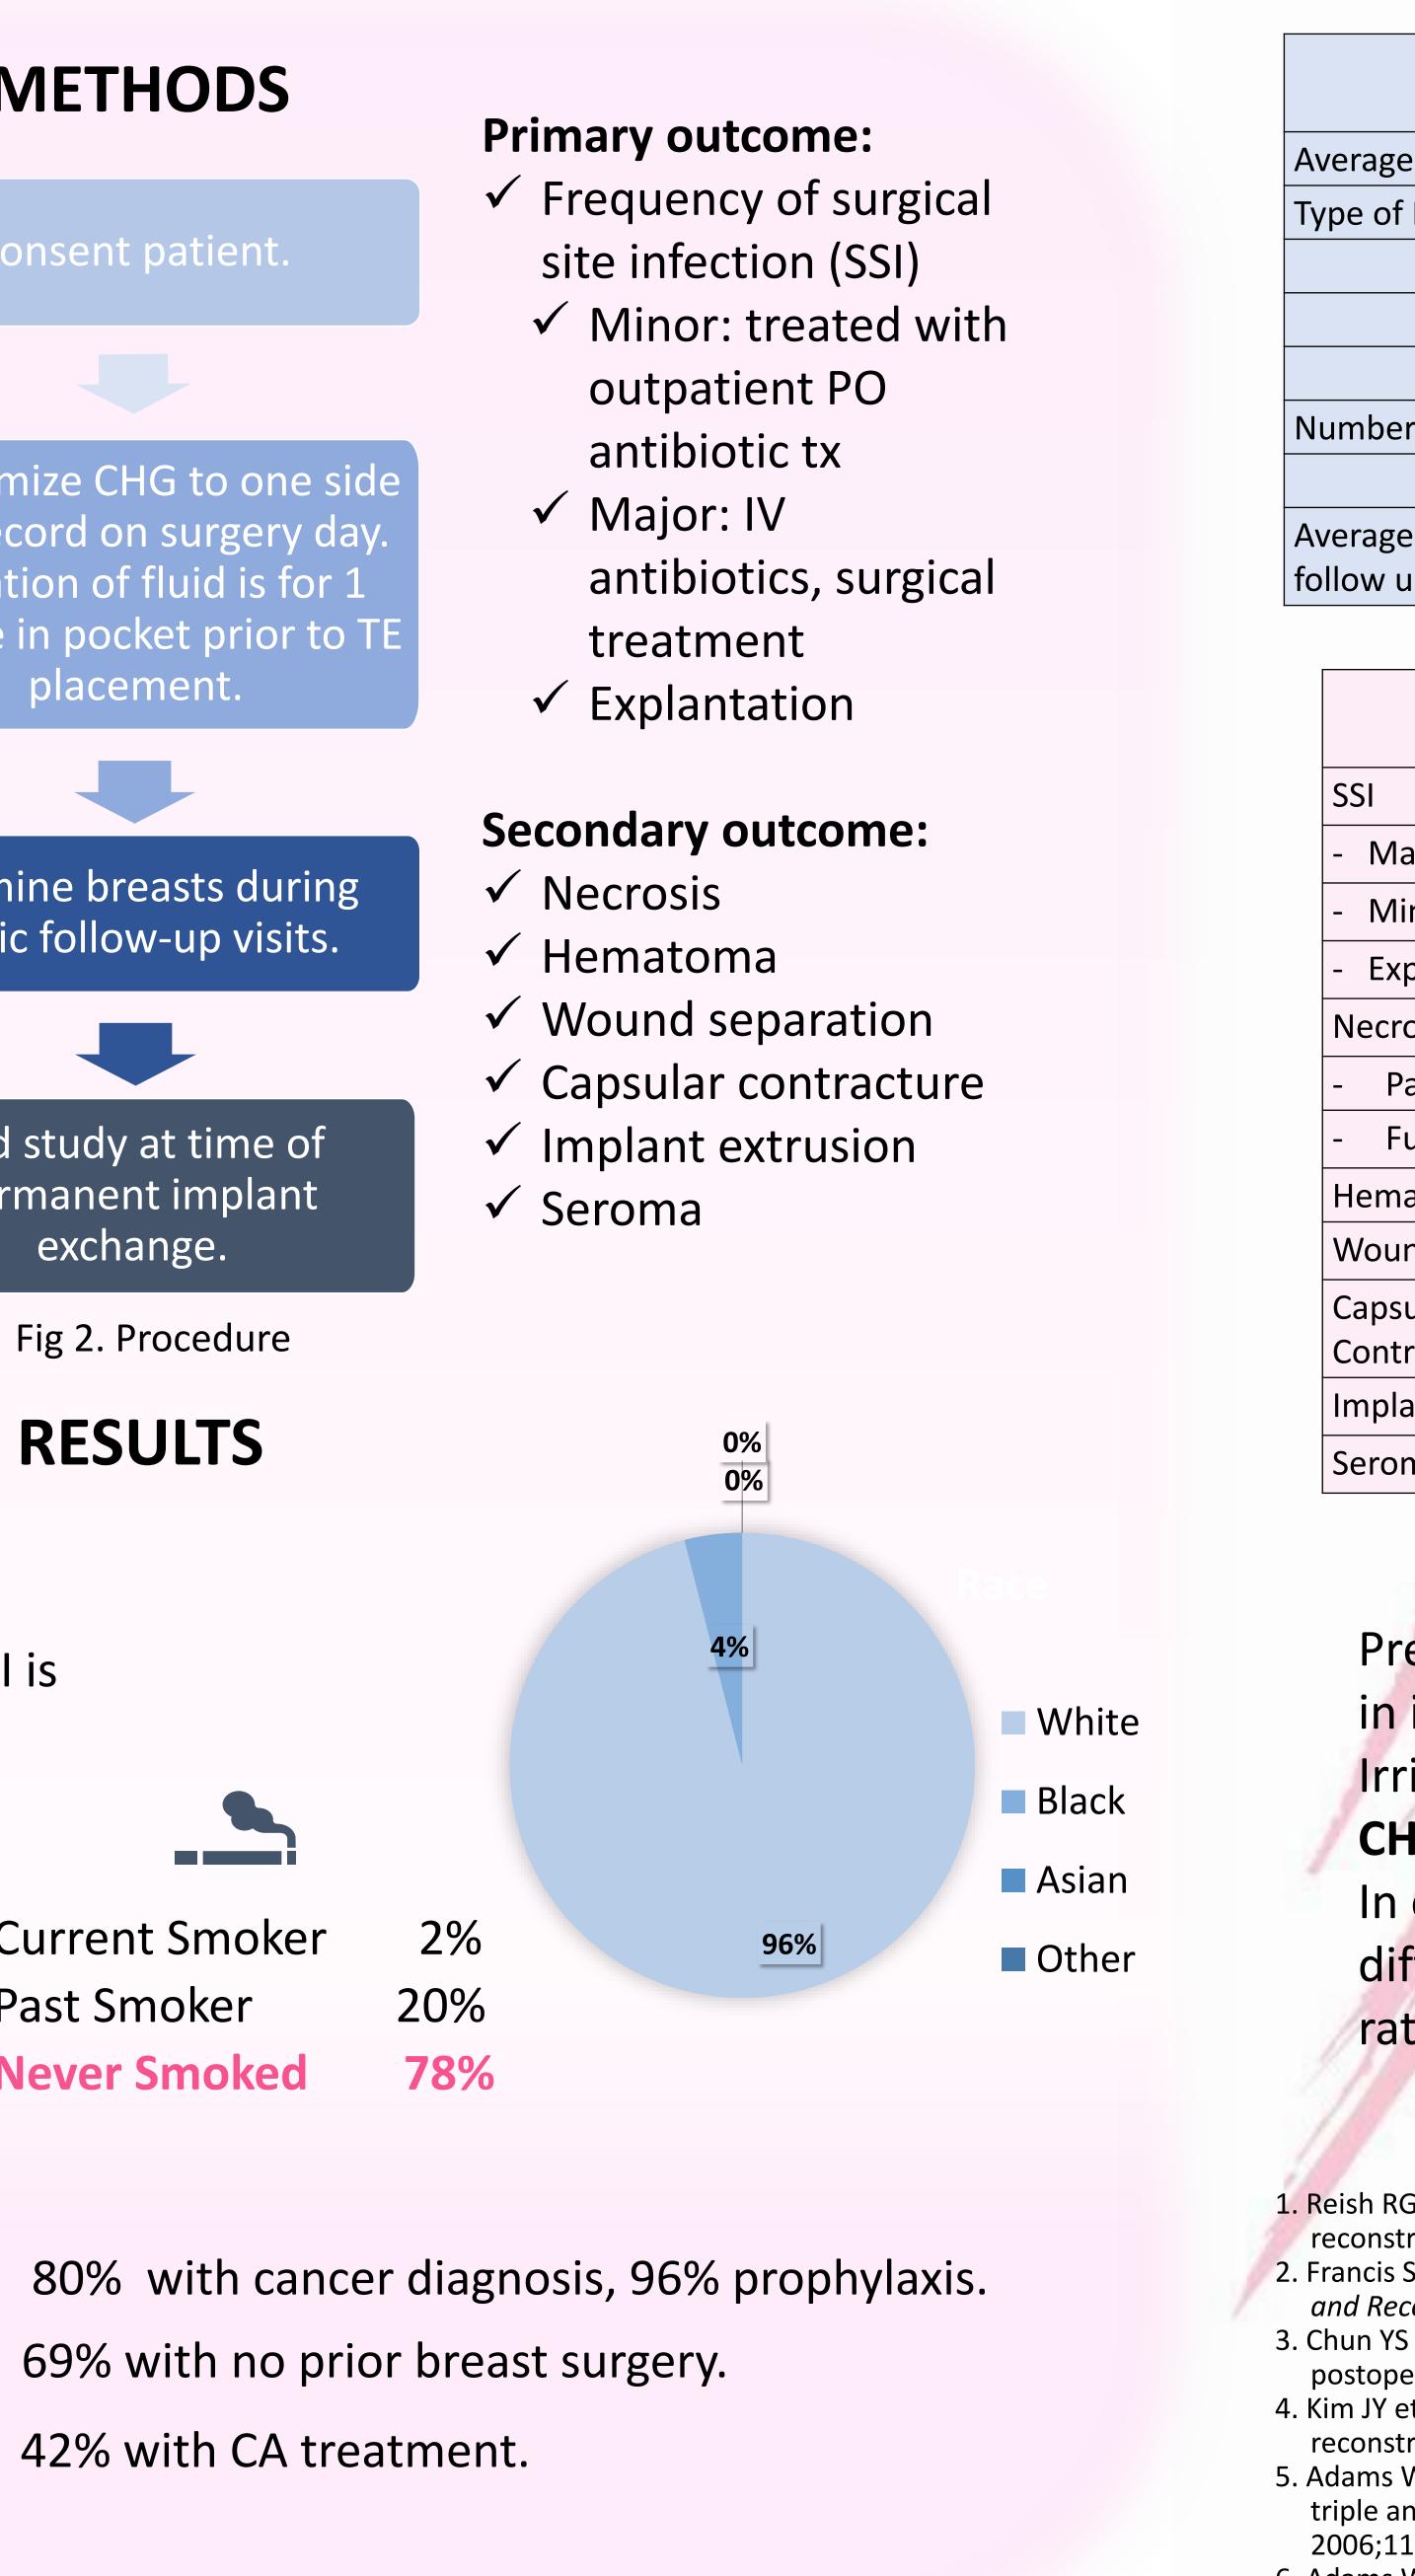

Pectoralis mus

 Perform a prospective, randomized study comparing incidence of surgical wound infection between mastectomy wounds irrigated with tr antibiotic solution (one side) and 0.05% CHG (contralateral side) in patients undergoing bre reconstruction

✓ Clinical trials: NCT02395614

CONCLUSION

Preliminary data demonstrates **no significant difference** in infection rate between CHG and Triple Antibiotic Irrigation though trends showed decreased infection in CHG group.

In order to reach adequate power to demonstrate a true difference with the use of chlorhexidine with infection rates, enrollment is to continue.
